University of Cambridge

## Applications of Continuations

---

# Applications of Continuations

We have seen that:

- Classical logic has a beautiful inference system
- Embeds into constructive logic via double-negation translations
- This yields an operational interpretation
- What can we program with continuations?

# The Typed Lambda Calculus with Continuations

Types       $X ::= 1 \mid X \times Y \mid 0 \mid X + Y \mid X \rightarrow Y \mid \neg X$

Terms       $e ::= x \mid \langle \rangle \mid \langle e, e \rangle \mid \text{fst} e \mid \text{snd} e$   
              | abort |  $\text{L} e$  |  $\text{R} e$  | case( $e, \text{L} x \rightarrow e', \text{R} y \rightarrow e''$ )  
              |  $\lambda x : X. e$  |  $e e'$   
              | throw( $e, e'$ ) | letcont $x. e$

Contexts     $\Gamma ::= \cdot \mid \Gamma, x : X$

# Continuation Typing

$$\frac{\Gamma, u : \neg X \vdash e : X}{\Gamma \vdash \text{letcont } u : \neg X. e : X} \text{CONT}$$

$$\frac{\Gamma \vdash e : \neg X \quad \Gamma \vdash e' : X}{\Gamma \vdash \text{throw}_Y(e, e') : Y} \text{THROW}$$

# Continuation API in Standard ML

```
1   signature CONT = sig
2     type 'a cont
3     val callcc : ('a cont -> 'a) -> 'a
4     val throw : 'a cont -> 'a -> 'b
5   end
```

SML	Type Theory
'a cont	$\neg A$
throw k v	$\text{throw}(k, v)$
callcc (fn x => e)	$\text{letcont} x : \neg X. e$

# An Inefficient Program

```
1   val mul : int list -> int
2
3   fun mul []          = 1
4       | mul (n :: ns) = n * mul ns
```

- This function multiplies a list of integers
- If 0 occurs in the list, the whole result is 0

# A Less Inefficient Program

```
1     val mul' : int list -> int
2
3     fun mul' []          = 1
4         | mul' (0 :: ns) = 0
5         | mul' (n :: ns) = n * mul' ns
```

- This function multiplies a list of integers
- If 0 occurs in the list, it immediately returns 0
  - `mul' [0,1,2,3,4,5,6,7,8,9]` will immediately return
  - `mul' [1,2,3,4,5,6,7,8,9,0]` will multiply by 0, 9 times

## Even Less Inefficiency, via Escape Continuations

```
1  val loop = fn : int cont -> int list -> int
2  fun loop return []          = 1
3  | loop return (0 :: ns) = throw return 0
4  | loop return (n :: ns) = n * loop return ns
5
6  val mul_fast : int list -> int
7  fun mul_fast ns = callcc (fn ret => loop ret ns)
```

- `loop` multiplies its arguments, unless it hits 0
- In that case, it throws 0 to its continuation
- `mul_fast` captures its continuation, and passes it to `loop`
- So if `loop` finds 0, it does no multiplications!

## McCarthy's amb Primitive

- In 1961, John McCarthy (inventor of Lisp) proposed a language construct `amb`
- This was an operator for *angelic nondeterminism*

```
1      let val x = amb [1,2,3]
2          val y = amb [4,5,6]
3          in
4              assert (x * y = 10);
5              (x, y)
6          end
7      (* Returns (2,5) *)
```

- Does search to find a successful assignment of values
- Can be implemented via backtracking – *using continuations*

# The AMB signature

```
1  signature AMB = sig
2      (* Internal implementation *)
3      val stack : int option cont list ref
4      val fail : unit -> 'a
5
6      (* External API *)
7      exception AmbFail
8      val assert : bool -> unit
9      val amb : int list -> int
10 end
```

# Implementation, Part 1

```
1 exception AmbFail
2 val stack
3   : int option cont list ref
4 = ref []
5
6 fun fail () =
7   case !stack of
8     []          => raise AmbFail
9     | (k :: ks) => (stack := ks;
10                      throw k NONE)
11
12 fun assert b =
13   if b then () else fail()
```

- `AmbFail` is the failure exception for unsatisfiable computations
- `stack` is a stack of backtrack points
- `fail` grabs the topmost backtrack point, and resumes execution there
- `assert` backtracks if its condition is false

# Implementation, Part 2

```
1 fun amb []          = fail ()  
2 | amb (x :: xs) =  
3   let fun next y k =  
4     (stack := k :: !stack;  
5      SOME y)  
6   in  
7   case callcc (next x) of  
8     SOME v => v  
9   | NONE => amb xs  
10 end
```

- `amb []` backtracks immediately!
- `next y k` pushes `k` onto the backtrack stack, and returns `SOME y`
- Save the backtrack point, then see if we immediately return, or if we are resuming from a backtrack point and must try the other values

## Examples

```
1  fun test2() =
2      let val x = amb [1,2,3,4,5,6]
3          val y = amb [1,2,3,4,5,6]
4          val z = amb [1,2,3,4,5,6]
5      in
6          assert(x + y + z >= 13);
7          assert(x > 1);
8          assert(y > 1);
9          assert(z > 1);
10         (x, y, z)
11     end
12
13 (* Returns (2, 5, 6) *)
```

# Conclusions

- `amb` required the *combination* of state and continuations
- Theorem of Andrzej Filinski that this is **universal**
- Any “definable monadic effect” can be expressed as a combination of state and first-class control:
  - Exceptions
  - Green threads
  - Coroutines/generators
  - Random number generation
  - Nondeterminism

# Dependent Types

---

# The Curry Howard Correspondence

Logic	Language
Intuitionistic Propositional Logic	STLC
Classical Propositional Logic	STLC + 1 <sup>st</sup> class continuations
Pure Second-Order Logic	System F

- Each logical system has a corresponding computational system
- One thing is missing, however
- Mathematics uses quantification over *individual elements*
- Eg,  $\forall x, y, z, n \in \mathbb{N}$ . if  $n > 2$  then  $x^n + y^n \neq z^n$

# A Logical Curiosity

$$\frac{}{\Gamma \vdash z : \mathbb{N}} \text{NI}_z$$

$$\frac{\Gamma \vdash e : \mathbb{N}}{\Gamma \vdash s(e) : \mathbb{N}} \text{NI}_s$$

$$\frac{\Gamma \vdash e_0 : \mathbb{N} \quad \Gamma \vdash e_1 : X \quad \Gamma, x : X \vdash e_2 : X}{\Gamma \vdash \text{iter}(e_0, z \rightarrow e_1, s(x) \rightarrow e_2) : X} \text{NE}$$

- $\mathbb{N}$  is the type of natural numbers
- Logically, it is equivalent to the unit type:
  - $(\lambda x : 1. z) : 1 \rightarrow \mathbb{N}$
  - $(\lambda x : \mathbb{N}. \langle \rangle) : \mathbb{N} \rightarrow 1$
- Language of types has no way of distinguishing  $z$  from  $s(z)$ .

# Dependent Types

- Language of types has no way of distinguishing  $z$  from  $s(z)$ .
- So let's fix that: let types refer to values
- Type grammar and term grammar mutually recursive
- Huge gain in expressive power

# An Introduction to Agda

- Much of earlier course leaned on prior knowledge of ML for motivation
- Before we get to the theory of dependent types, let's look at an implementation
- Agda: a dependently-typed functional programming language
- **http://wiki.portal.chalmers.se/agda/pmwiki.php**

# Agda: Basic Datatypes

```
1  data Bool : Set where
2    true : Bool
3    false : Bool
4
5  not : Bool → Bool
6  not true = false
7  not false = true
```

- Datatype declarations give constructors and their types
- Functions given type signature, and clausal definition

# Agda: Inductive Datatypes

```
1  data Nat : Set where
2    z : Nat
3    s : Nat → Nat
4
5    _+_ : Nat → Nat → Nat
6    z + m = m
7    s n + m = s (n + m)
8
9    _*_ : Nat → Nat → Nat
10   z * m = z
11   s n * m = m + (n * m)
```

- Datatype constructors can be recursive
- Functions can be recursive, but checked for termination

# Agda: Polymorphic Datatypes

```
1  data List (A : Set) : Set where
2    [] : List A
3    _,_ : A → List A → List A
4
5    app : (A : Set) → List A → List A → List A
6    app A [] ys = ys
7    app A (x , xs) ys = x , app A xs ys
8
9    app' : {A : Set} → List A → List A → List A
10   app' [] ys = ys
11   app' (x , xs) ys = (x , app' xs ys)
```

- Datatypes can be polymorphic
- **app** has F-style explicit polymorphism
- **app'** has implicit, inferred polymorphism

# Agda: Indexed Datatypes

```
1  data Vec (A : Set) : Nat → Set where
2    [] : Vec A z
3    _,_ : {n : Nat} → A → Vec A n → Vec A (s n)
```

- This is a *length-indexed list*
- Cons takes a head and a list of length  $n$ , and produces a list of length  $n + 1$
- The empty list has a length of 0

## Agda: Indexed Datatypes

```
1  data Vec (A : Set) : Nat → Set where
2    [] : Vec A z
3    _,_ : {n : Nat} → A → Vec A n → Vec A (s n)
4
5  head : {A : Set} → {n : Nat} → Vec A (s n) → A
6  head (x , xs) = x
```

- `head` takes a list of length  $> 0$ , and returns an element
- No `[]` pattern present
- Not needed for coverage checking!
- Note that `{n:Nat}` is *also* an implicit (inferred) argument

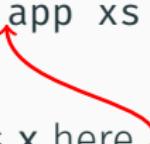

# Agda: Indexed Datatypes

```
1  data Vec (A : Set) : Nat → Set where
2    [] : Vec A z
3    _,_ : {n : Nat} → A → Vec A n → Vec A (s n)
4
5    app : {A : Set} → {n m : Nat} →
6          Vec A n → Vec A m → Vec A (n + m)
7    app [] ys = ys
8    app (x , xs) ys = (x , app xs ys)
```

- Note the appearance of  $n + m$  in the type
- This type guarantees that appending two vectors yields a vector whose length is the sum of the two

# Agda: Indexed Datatypes

```
1  data Vec (A : Set) : Nat → Set where
2    [] : Vec A z
3    _,_ : {n : Nat} → A → Vec A n → Vec A (s n)
4
5  -- Won't typecheck!
6  app : {A : Set} → {n m : Nat} →
7    Vec A n → Vec A m → Vec A (n + m)
8  app [] ys = ys
9  app (x , xs) ys = app xs ys
```

- 
- We forgot to cons  $x$  here
  - This program won't type check!
  - Static typechecking ensures a runtime guarantee

# The Identity Type

```
data _≡_ {A : Set} (a : A) : A → Set where
  refl : a ≡ a
```

- $a \equiv b$  is the type of proofs that  $a$  and  $b$  are equal
- The constructor `refl` says that a term  $a$  is equal to itself
- Equalities arising from evaluation are automatic
- Other equalities have to be **proved**

# An Automatic Theorem

```
data _≡_ {A : Set} (a : A) : A → Set where
  refl : a ≡ a
```

\_+\_ : Nat → Nat → Nat

$$z + m = m$$

$$s\ n + m = s\ (n + m)$$

`z--left-unit : (n : Nat) → (z + n) ≡ n`

`z--left-unit n = refl`

- $z + n$  evaluates to  $n$

- So Agda considers these two terms to be identical

# A Manual Theorem

```
data _≡_ {A : Set} (a : A) : A → Set where
  refl : a ≡ a

cong : {A B : Set} → {a a' : A} →
      (f : A → B) → (a ≡ a') → (f a ≡ f a')
cong f refl = refl

z-->right-unit : (n : Nat) → (n + z) ≡ n
z-->right-unit z = refl
z-->right-unit (s n) = cong s (z-->right-unit n)
```

- We prove the right unit law inductively
- Note that *inductive proofs are recursive functions*
- To do this, we need to show that equality is a congruence

# The Equality Toolkit

```
data _≡_ {A : Set} (a : A) : A → Set where
  refl : a ≡ a

  sym : {A : Set} → {a b : A} →
    a ≡ b → b ≡ a
  sym refl = refl

  trans : {A : Set} → {a b c : A} →
    a ≡ b → b ≡ c → a ≡ c
  trans refl refl = refl

  cong : {A B : Set} → {a a' : A} →
    (f : A → B) → (a ≡ a') → (f a ≡ f a')
  cong f refl = refl
```

- An *equivalence relation* is a reflexive, symmetric transitive relation
- Equality is congruent with everything

# Commutativity of Addition

```
z-->right : (n : Nat) → (n + z) ≡ n
z-->right z = refl
z-->right (s n) =
  cong s (z-->right n)

s-->right : (n m : Nat) →
  (s (n + m)) ≡ (n + (s m))
s-->right z m = refl
s-->right (s n) m =
  cong s (s-->right n m)

+-comm : (i j : Nat) →
  (i + j) ≡ (j + i)
+-comm z j = z-->right j
+-comm (s i) j = trans p2 p3
  where p1 : (i + j) ≡ (j + i)
    p1 = +-comm i j
    p2 : (s (i + j)) ≡ (s (j + i))
    p2 = cong s p1
    p3 : (s (j + i)) ≡ (j + (s i))
    p3 = s-->right j i
```

- First we prove that adding zero on the right does nothing
- Then we prove that successor commutes with addition
- Then we use these two facts to inductively prove commutativity of addition

# Conclusion

- Dependent types permit referring to program terms in types
- This enables writing types which state very precise properties of programs
  - Eg, equality is expressible as a type
- Writing a program becomes the same as proving it correct
- This is hard, like learning to program again!
- But also extremely fun...
